

Smalltalk has a very simple model of inheritance  
 Here is an instance method.

`| anobject |` ← local variable  
`anobject := B new.` ← class name  
`anobject m1` ← class method  
 ↑ receiver      ↑ message

Class A supertype Object

instance variables: x

instance methods:

getX

^ x

Class B supertype A

instance variables: y

instance methods:

getY

^ y

every instance variable is private

every instance method is public

Smalltalk implements inheritance using a run-time search.

1. The receiver attempts to match the message with one of its class's methods.
2. If a match is found, its body is run and an object is returned.
3. If a match is not found, the message search continues in the superclass (and any other superclasses up the inheritance chain).
4. If the method is not found in Object, then a system error occurs.

## Method polymorphism in C++ (and Java)

- Late binding, where late  $\equiv$  run-time
- Smalltalk allows polymorphism because any message can be sent to any object

```
class A {
public:
    void f1();
};
```

```
class B : public A {
public:
    void f1();
};
```

```
class C : public A {
public:
    void f1();
};
```

```
A a1;
B b1;
C c1;
```

```
a1.f1();
b1.f1();
c1.f1();
```

} strong typing ensures that the f1 in the class of the receiver is called

```
a1 = b1;
```

```
a1.f1(); ← still calls f1 in A
```

```
a1 = c1;
```

```
a1.f1(); ← calls f1 in A
```

What about pointers?

A \*pa1 = new A();

B \*pb1 = new B();

C \*pc1 = new C();

pa1 → f1();

pb1 → f1();

pc1 → f1();

} call f1 in class  
corresponding to the object

pa1 = pb1;

pa1 → f1(); ← still call f1 in A

If we want to call f1 in B through pa1, then we need to declare f1 in A as "virtual"

```
class A {
```

```
public:
```

```
    virtual void f1();
```

```
};
```

A + pa1 = new A();

B + pb1 = new B();

pa1 → f1(); ← no call compiled but  
code to look up the correct  
function at run-time - calls  
f1 in A

pa1 = pb1;

pa1 → f1(); ← calls f1 in B

The compiler deposits RTTI so that the type of every object is stored with the object. Also a table of pointers to functions where virtual functions are declared. (The vTable)

This call (to f1) would fail if the corresponding function is not available

We can make a virtual function "pure" by giving it a null body: virtual void f1() = 0;

This makes the class abstract (no objects can be made)

Smalltalk : messages and methods

$$\begin{array}{c}
 \text{selector} \\
 2\ 1\ +\ 2 \leftarrow \text{argument} \\
 \uparrow \quad \downarrow \\
 \text{receiver} \quad \text{message}
 \end{array}$$

We can also have keyword messages

$$\begin{array}{c}
 \text{firstArray} \text{ at: } \text{index} - 1 \text{ put: } 77 \\
 \uparrow \qquad \qquad \qquad \underbrace{\hspace{10em}} \\
 \text{receiver} \qquad \qquad \qquad \text{message}
 \end{array}$$

The message selector is in two parts at: put:

The method might be declared as:

$$\begin{array}{c}
 \text{at: } \text{index} \text{ put: } \text{value} \\
 \uparrow \qquad \qquad \nearrow \\
 \text{parameter}
 \end{array}$$

It's exactly like `firstArray[index-1] = 77;`

- \* In general a message alters the instance variables of the receiver — the receiving object changes state.

Methods are stored in classes:

general form:

patterns [ | local vars | ] statement-body

e.g.

currentTotal

Unary message

^ (oldTotal + newValue).

x: xCoord y: yCoord

surpen up.

surpen goto: xCoord @ yCoord.

surpen down.

sending the x:y: message

obj x: 300 y: 400

Statements can be put into blocks, which are objects - they can be assigned to variables.

[ index := index + 1 . sum := sum + index ]

summer := [ ..... ]

summer value

new code in the block

### Iteration in Smalltalk

count := 1.

sum := 0.

[ count <= 20 ]

whileTrue: [ sum := sum + count .  
count := count + 1 ]
