Abstract
Most practical work on AI planning systems during the last fifteen years has been based on hierarchical task network (HTN) decomposition, but until now, there has been very little analytical work on the properties of HTN planners. This paper describes how the complexity of HTN planning varies with various conditions on the task networks.

Introduction
In AI planning research, planning practice (as embodied in implemented planning systems) tends to run far ahead of the theories that explain the behavior of these systems. There is much recent analysis of the properties of total- and partial-order planning systems using STRIPS-style planning operators—but STRIPS-style planning systems were developed more than 20 years ago, and most of the practical work on AI planning systems during the last fifteen years has been based on hierarchical task network (HTN) decomposition (e.g., NOAH(Sacerdoti, 1990), NONLIN(Tate, 1990), sipe(Wilkins, 1988), and DEVISER(Vere, 1983)).

Until now, there has been very little analytical work on the properties of HTN planners. One of the primary obstacles impeding such work has been the lack of a clear theoretical framework explaining what a HTN planning system is, although two recent papers (Yang, 1990; Kambhampati et al., 1992) have provided important first steps in that direction. A primary goal of our current work is to correctly define, analyze, and elucidate features of the design of HTN planning systems.

Our work has progressed far enough that we can do complexity analyses of HTN planning similar to analyses which Erol et al. (1992) performed for planning with STRIPS-style operators. In particular, Table 1 shows how the complexity of telling whether a plan exists depends on the following factors: (1) restrictions on the existence and/or ordering of non-primitive tasks in task networks, (2) whether the tasks in task networks are required to be totally ordered, and (3) whether variables are allowed. From this table, we can draw the following conclusions:

1. HTN’s are more expressive than STRIPS-style operators. This contradicts the idea, held by some researchers, that HTN’s are just an “efficiency hack.”

2. HTN planning is undecidable under even a very severe set of constraints. In particular, it is undecidable even if no variables are allowed, as long as there is the possibility that a task network can contain two non-primitive tasks without specifying the order in which they must be performed.

3. In general, what restrictions we put on the non-primitive tasks has a bigger effect on complexity than whether or not we allow variables, or require tasks to be totally ordered.

4. To achieve decidability, it is sufficient to place restrictions either on non-primitive tasks or on the ordering of tasks. If either restriction is removed individually, planning remains decidable, but removing both simultaneously makes planning undecidable.

5. If there are no restrictions on non-primitive tasks, then whether or not we require tasks to be totally ordered has a bigger effect (namely, decidability vs. undecidability) than whether or not we allow variables. But in the presence of restrictions on non-primitive tasks, whether or not we allow variables has a bigger effect than whether or not we require tasks to be totally ordered.

Basics of HTN Planning

Overview
To provide an intuitive feel for HTN planning, here is a deliberately oversimplified description. The “Details” section gives a more precise description.

The input to the planner consists of the following:

- An initial “task network” d representing the problem to be solved. A task network is a set of “tasks” representing things that need to be done. Each task is a task name along with a list of arguments, which may

be variables or constants. Some tasks are “primitive” (i.e., they can be performed directly), and others are “non-primitive” (i.e., the planner needs to figure out how to perform them). Task networks also include constraints on the tasks, which may restrict how some of the variables can be bound, the order in which the tasks are to be performed, etc.

- A set of “operators” $Op$ telling the effects of each primitive task (action).
- A set of “methods” $Me$ telling how to perform various non-primitive tasks. Each method is a pair $m = (t, d)$, where $t$ is a task and $d$ is a task network. It says one way to achieve $t$ is to perform the tasks specified in the network $d$ (provided that this can be done in a way that satisfies all the constraints).

Planning proceeds by starting with the initial task network $d$, and doing the following steps repeatedly, until no non-primitive tasks are left: find a non-primitive task $u$ in $d$ and a method $m = (t, d')$ in $M$ such that $t$ unifies with $u$. Then modify $d$ by “reducing” $u$ (i.e., replace $u$ with the tasks in $d'$, and incorporate the constraints of $d'$ into $d$). Once no non-primitive tasks are left in $d$, the next problem is to find a totally-ordered ground instantiation $\sigma$ of $d$ that satisfies all of the constraints. If this can be done, then $\sigma$ is a successful plan for the original problem.

In practice, HTN planning also has several other aspects. In particular, functions are often provided which can “debug” partially reduced task networks to eliminate potential problems. These “critic” functions are used to handle ordering constraints, resource limits, and to provide domain-specific guidance. The formalization described in (Erol et al., 1994a) explains critics and the relationship between these and the constraints described above. For the purposes of this paper, the critics do not affect worst-case behavior, and thus we will omit this detail.

Details

Our language $\mathcal{L}$ for HTN planning is a first-order language with some extensions. The representations of the world and the actions in HTN planning is very similar to those of STRIPS-style planning. Thus, $\mathcal{L}$ contains a set $C$ of constant symbols that represent the objects, and a set $P$ of predicate symbols that represent the relations among the objects. $\mathcal{L}$ also contains a set $F$ of primitive task symbols which represent the actions. We use constructs called operators to associate effects to primitive task symbols. We define a plan as a sequence of ground primitive tasks, and we designate the initial state of the world by a list of ground atoms.

The fundamental difference between STRIPS-style planning and HTN planning is the representation of “desired change” in the world. HTN planning replaces STRIPS-style “goals” with tasks and task networks (which we later show are more powerful). There are three types of tasks:

- **Goal tasks**, like goals in STRIPS, are properties we wish to make true in the world (for example, having a new house).
- **Primitive tasks** are the tasks we can directly achieve by executing the corresponding action, such as moving a block, or turning a switch on.
- **Compound tasks** denote desired changes that involve several goal tasks and primitive tasks; e.g., building a house requires many other tasks to be performed (laying the foundation, building the walls, etc.). Compound tasks allows us to represent “desired changes” that can not be represented as a single goal task or primitive task. As an example, the compound task of “building a house” is different from the goal task of “having a house,” since buying a house would achieve the goal task, but not the compound task. As another example, the compound task of making a round trip to New York cannot easily be expressed as a single goal task, because the initial and final states would be the same.

Formally, the vocabulary of HTN language $\mathcal{L}$ is a tuple $(\mathcal{V}, \mathcal{C}, \mathcal{P}, F, T, N)$, where $\mathcal{V} = \{v_1, v_2, \ldots\}$ is an infinite set of variable symbols, $\mathcal{C}$ is a finite set of constant symbols, $\mathcal{P}$ is a finite set of predicate symbols, $F$ is a finite set of primitive task symbols, $T$ is a finite set of compound task symbols, and $N = \{n_1, n_2, \ldots\}$ is
an infinite set of symbols used for labeling tasks. If \( x_1, \ldots, x_k \) are terms, then a primitive task has the form 
\[
do(f(x_1, \ldots, x_k)), \quad f \in F; \text{ a goal task has the form } \text{achieve}(l), \text{ where } l \text{ is a literal; and a compound task has the form } \text{perform}([x_1, \ldots, x_k]), \text{ where } t \in T.
\]
We refer to goal tasks and compound tasks as non-primitive tasks.

Tasks are connected together in HTN planning via the use of task networks,\(^2\) which are collections of tasks and constraints on those tasks. Formally, a task network has the form \(((n_1 : \alpha_1), \ldots, (n_m : \alpha_m), \phi)\), where each \( \alpha_i \) is a task labeled with \( n_i \); and \( \phi \) is a boolean formula constructed from variable binding constraints such as \( v = v' \) and \( v = c \), temporal ordering constraints such as \( n < n' \), and truth constraints such as \( (n, l), (l, n) \), \( (n, l, n') \), \( (n, n') \), \( (n', l) \), \( (l, n) \) and \( (n, l, n') \) mean that \( l \) needs to be true immediately after \( n \), immediately before \( n' \), and between \( n' \) and \( n' \), respectively. Both negation and disjunction are allowed in the constraint formula.

As an example, Fig. 1 shows a blocks-world task network and its graphical representation. In this task network there are three tasks: clearing \( v_1 \), clearing \( v_2 \), and moving \( v_1 \) to \( v_2 \). The task network also includes the constraints that moving \( v_1 \) should be done last, \( v_1 \) and \( v_2 \) should remain clear until we move \( v_1 \), and that the variable \( v_3 \) is bound to the location of \( v_1 \) before \( v_1 \) is moved.

To specify how actions change the world, we use operators of the form \((f(v_1, \ldots, v_k), l_1, \ldots, l_m)\), where \( f \) is a primitive task symbol, \( v_1, \ldots, v_k \) are variable symbols, and \( l_1, \ldots, l_m \) are literals, denoting the primitive task’s effects (which are also called postconditions). Our HTN operators do not contain STRIPS-style preconditions; preconditions are realized as goal tasks in task networks (as in Fig. 1).

It is clear how to achieve a primitive task: execute the corresponding action. But for non-primitive tasks, we need to tell our planner how to achieve them, and we do this using constructs called methods.

A method is a pair \((\alpha, d)\) where \( \alpha \) is a non-primitive task, and \( d \) is a task network. It states that one way of achieving the task \( \alpha \) is to achieve the task network \( d \), i.e. to achieve all the subtasks in the task network without violating the constraint formula of the task network. For example, a blocks-world method for achieving \((\text{on}(v_1, v_2))\) would look like \((\text{achieve}([\text{on}(v_1, v_2)]), d)\), where \( d \) is the task network in Fig. 1. An empty plan would achieve a goal task when the goal is already true. Thus, for each goal task, we (implicitly) have a method \((\text{achieve}(l), (l : \text{done}(l))(l, n))\) which contains only one dummy primitive task \( t \) with no effects, and the constraint that the goal \( l \) is true immediately before \( t \).

### Planning Domains and Problems

A planning domain is a pair \( D = (\mathcal{O}_p, \mathcal{M}_e) \), where \( \mathcal{O}_p \) is a set of operators, and \( \mathcal{M}_e \) is a set of methods.

A planning problem is a triple \( P = (d, I, D) \), where \( D \) is a planning domain, \( I \) is the initial state, and \( d \) is the task network we need to plan for. The language of \( P \) is the HTN language \( \mathcal{L} \) generated by the constant, predicate, and task symbols appearing in \( P \), along with an infinite set of variables and an infinite set of node labels. Thus, the set of constants, predicates and tasks are all part of the input.

\( P \) is primitive if the task network \( d \) contains only primitive tasks. \( P \) is regular if all the task networks in the methods and \( d \) contain at most one non-primitive task, and that non-primitive task is ordered to occur as either the first or the last task. \( P \) is propositional if no variables are allowed. \( P \) is totally ordered if all the tasks in any task network are totally ordered.

**PLAN EXISTENCE** is the following problem: given \( P = (d, I, D) \), is there a plan that solves \( P \)?

The problem of finding an optimal (i.e., shortest-length) plan that solves \( P \) is at least as difficult as the problem of determining whether or not a plan exists. In an analysis of STRIPS-style planning, Erol et al. (1992) analyzed this problem by transforming it into a decision problem (which we called PLAN LENGTH) according to the usual complexity-theoretic technique of asking whether, for some input integer \( k \), there exists a successful plan of length \( k \) or less.

This paper does not address the plan optimality problem, for two reasons. First, HTN planners have usually not worried about optimality because it is so difficult to verify (in many cases, optimality cannot be guaranteed by method decomposition). Second, Erol et al. (1992) found that for STRIPS-style planning, in some cases the complexity of PLAN LENGTH was misleadingly low. In particular, PLAN LENGTH was NP-EXPTIME-complete even in cases where the plan optimality problem was much harder, because the input
to PLAN LENGTH includes the integer \( k \) encoded in binary, which confines the planner to plans of length at most exponential in the length of the input.

**Operational Semantics**

In this section, we give a syntactic characterization of the set of solutions for a given HTN-planning problem. Description of an equivalent model-theoretic semantics appear in (Erol et al., 1994a).

Let \( \sigma \) be a primitive task network (one containing only primitive tasks), and let \( I \) be the initial state. A plan \( \sigma \) is a completion of \( d \) at \( I \), denoted by \( \sigma \in \text{comp}(d, I, D) \), if \( \sigma \) is a total ordering of the primitive tasks in a ground instance of \( d \) that satisfies the constraint formula of \( d \).

Let \( d \) be a non-primitive task network that contains a (non-primitive) node \((n: \alpha)\). Let \( m = (\alpha', \alpha') \) be a method, and \( \theta \) be the most general unifier of \( \alpha \) and \( \alpha' \). Then we define \( \text{reduce}(d, n, m) \) to be the task network obtained from \( d \theta \) by replacing \((n: \alpha)\) \( \theta \) with the task nodes of \( d \theta \), and incorporating \( d \theta \)'s constraint formula into the constraint formula of \( d \). We denote the set of reductions of \( d \) by \( \text{red}(d, I, D) \). Reductions formalize the notion of task decomposition. For a precise definition of completions and reductions, the reader is referred to (Erol et al., 1994a).

Here are the two inference rules we use to find plans:

**R1.** If \( \sigma \in \text{comp}(d, I, D) \), conclude \( \sigma \in \text{sol}(d, I, D) \).

**R2.** If \( d' \in \text{red}(d, I, D) \) and \( \sigma \in \text{sol}(d', I, D) \), conclude \( \sigma \in \text{sol}(d, I, D) \).

Rule R1 says that the set of plans that achieve a primitive task network consists of the completions of the task network; Rule R2 says that if \( d' \) is a reduction of \( d \), then any plan that achieves \( d' \) also achieves \( d \).

Now, we need to define the set of plans that can be derived using those two inference rules. Let us define a function \( \text{sol}(d, I, D) \) as follows:

\[
\text{sol}_1(d, I, D) = \text{comp}(d, I, D) \\
\text{sol}_{n+1}(d, I, D) = \text{sol}_n(d, I, D) \cup \bigcup_{d' \in \text{red}(d, I, D)} \text{sol}_n(d', I, D) \\
\text{sol}(d, I, D) = \bigcup_{n \geq 0} \text{sol}_n(d, I, D)
\]

Intuitively, \( \text{sol}_n(d, I, D) \) is the set of plans that can be derived in \( n \) steps, and \( \text{sol}(d, I, D) \) is the set of plans that can be derived in any finite number of steps. (Erol et al., 1994a) it is proved that \( \text{sol}(d) \) is indeed the set of solutions, and that the inference rules R1, R2 are sound and complete.

**Results**

**Decidability**

It is easy to show that we can simulate context-free grammars within HTN planning. More interesting is the fact that we can simulate any two context-free grammars, and with the help of task interleavings and constraints, we can check whether these two grammars have a common string in the languages they generate. Whether the intersection of the languages of two context-free grammars is non-empty is a semi-decidable problem (Hopcroft et al., 1979). Thus:

**Theorem 1** PLAN EXISTENCE is strictly semi-decidable, even if \( P \) is restricted to be propositional, to have at most two tasks in any task network, and to be totally ordered (except for the input task network).

One way to make PLAN EXISTENCE decidable is to restrict the methods to be acyclic. In that case, any task can be expanded up to a finite depth, and thus the problem becomes decidable. To this end, we define a \( k \)-level-mapping to be a function level() from ground instances of tasks to the set \([0, \ldots, k]\), such that whenever we have a method that can expand a ground task \( t \) to a task network containing a ground task \( t' \), level(t) \( > \) level(t'). Furthermore, level(t) must be 0 for every primitive task \( t \).

Intuitively, level() assigns levels to each ground task, and makes sure that tasks can be expanded into only lower level tasks, establishing an acyclic hierarchy. In this case, any task can be expanded to a depth of at most \( k \). Therefore,

**Theorem 2** PLAN EXISTENCE is decidable if \( P \) has a \( k \)-level-mapping for some finite integer \( k \).

Another way to make PLAN EXISTENCE decidable is to restrict the interactions among the tasks. Restricting the task networks to be totally ordered limits the interactions that can occur between tasks. Tasks need to be achieved serially, one after the other; interleaving subtasks for different tasks is not possible. Thus interactions between the tasks are limited to the input and output state of the tasks, and the “protection intervals”, i.e. the literals that need to be preserved.

Under the above conditions, we can create a table with an entry for each task, input/output state pair, and set of protected literals, that tells whether it is possible to achieve that task under those conditions. Using dynamic programming techniques we can compute the entries in the table in DOUBLE-EXPTIME, or in EXP-TIME if the problem is further restricted to be propositional. It is easy to show that STRIPS-style planning can be modeled using HTN’s that satisfy these conditions, so we can use the complexity results on STRIPS-style planning in (Erol et al., 1992) to establish a lower bound on the complexity of HTN planning. Thus:

**Theorem 3** PLAN EXISTENCE is EXPSPACE-hard and in DOUBLE-EXPTIME if \( P \) is restricted to be totally ordered. PLAN EXISTENCE is PSPACE-hard and in EXP-TIME if \( P \) is further restricted to be propositional.

If we restrict our planning problem to be regular, then there will be at most one non-primitive task in any task network (both the initial input task network,

\[3\] All proofs appear in (Erol et al., 1994b).
and those we obtain by expansions). Thus, subtasks in
the expansions of different tasks cannot be interleaved,
which is similar to what happens in Theorem 3. But in
Theorem 3, there could be several non-primitive tasks
in a task network, and we needed to keep track of all of
them (which is why we used the table). If the planning
problem is regular, we only need to keep track of a sin-
gle non-primitive task, its input-final states, and the
protected literals. Since the size of a state is at most
exponential, the problem can be solved in exponential
space. But even with regularity and several other
restrictions, it is still possible to reduce an EXPSPACE-
complete STRIPS-style planning problem (described
in (Erol et al., 1992)) to the HTN framework. Thus:

**Theorem 4** PLAN existence is EXPSPACE-complete
if $P$ is restricted to be regular. It is still EXPSPACE-
complete if $P$ is further restricted to be totally or-
dered, with at most one non-primitive task symbol in
the planning language, and all task networks contain-
ing at most two tasks.

When we further restrict our problem to be proposi-
tional, the complexity goes down one level:

**Theorem 5** PLAN existence is PSPACE-complete if
$P$ is restricted to be regular and propositional. It is
still PSPACE-complete if $P$ is further restricted to be
totally ordered, with at most one non-primitive task
symbol in the planning language, and all task networks
containing at most two tasks.

Suppose a planning problem is primitive, and either
propositional or totally ordered. Then the problem’s
membership in NP is easy to see: once we nondeter-
mministically guess a total ordering and variable bind-
ing, we can check whether the constraint formula on
the task network is satisfied in polynomial time. Fur-
thermore, unless we require the planning problem to be
both totally ordered and propositional, our constraint
language enables us to represent the satisfiability prob-
lem, and thus we get NP-hardness. Hence:

**Theorem 6** PLAN existence is NP-complete if $P$
is restricted to be primitive, or primitive and totally or-
dered, or primitive and propositional. However, PLAN
existence can be solved in polynomial time if $P$ is
restricted to be primitive, totally ordered, and propo-
sitional.

**Expressivity**

It has been informally observed that HTN approaches
do not need to completely specify the conditions that
each action affects, while the STRIPS-style “state-
based” plan structures typically require complete spec-
ification of intermediate states. Thus, in describing
the relationships between actions, it has been argued
that HTN approaches are more appropriate. Lansky
(1988), for example, makes this argument and claims
it is largely responsible for the more general use of
HTNs over STRIPS-style systems in planning practice.

Despite such claims, it has never been demonstrated
that HTNs can encode situations which STRIPS-style
planning operators cannot, because the lack of a for-
malism for HTN planning has left it unclear what can
be expressed with HTNs. Using the formalism in this
paper, we can directly compare the expressive power
of HTN and STRIPS-style planning operators.

When we compare HTNs and STRIPS, we observe that
the HTN approach provides all the concepts (states, ac-
tions, goals) that STRIPS has. In fact, given a domain
encoded as a set of STRIPS operators, we can transform
it to an HTN planning domain, in low-order poly-
nomial time. A straightforward transformation would be
to declare one primitive task symbol for each STRIPS
operator, and for every effect of each operator, to de-
clare a method similar to the one in Fig. 1. Each such
method contains the preconditions of the operator as
goal tasks, and also the primitive task corresponding
to the operator itself.

Below is a more instructive transformation, which
demonstrates that the relationship between STRIPS-
style planning and HTN planning is analogous to the
relationship between right linear (regular) grammars
and context-free grammars. We summarize the trans-
formation below; for details see (Erol et al., 1994b).

In this transformation, the HTN representation uses
the same constants and predicates used in the STRIPS
representation. For each STRIPS operator $o$, we declare
a primitive task $f$ with the same effects as $o$. We also
use a dummy primitive task $f_d$ with no effects. We
declare a single compound task symbol $t$. For each
primitive task $f$, we construct a method of the form

$$\text{perform}[t] \implies \text{do}[f] \quad \text{perform}[t]$$

where $t_1, \ldots, t_k$ are the preconditions of the action
associated with $f$. We declare one last method

$$\text{perform}[t] \implies \text{do}[f_d].$$

Note that $t$ can be expanded to any sequence of actions ending with $f_d$, pro-
vided that the preconditions of each action are sat-
isfied. The input task network has the form $[n : \text{perform}[t], (n, G_i) \land \ldots \land (n, G_m)]$ where $G_1, \ldots, G_m$
are the STRIPS-style goals we want to achieve. Note that
the transformation produces regular HTN problems,
which has exactly the same complexity as STRIPS-style
planning. Thus, just as restricting context-free gram-
mars to be right linear produces regular sets, restrict-
ing HTN methods to be regular produces STRIPS-style
planning.

HTNs can express situations impossible to express
using unmodified STRIPS operators. Intuitively, this is
because STRIPS lacks the concept of compound tasks,
and its notion of goals is limited. It does not provide
means for declaring goals/constraints on the interme-
diate states as HTNs do. Furthermore, in contrast to
STRIPS, HTNs provide a rich constraint language that
can express many types of interactions.
More formally, from Theorem 1, HTN planning with no function symbols (and thus only finitely many ground terms) is semi-decidable. Even if we require the domain description $\mathcal{D}$ to be fixed in advance (i.e., not part of the input), there are HTN planning domains for which planning is semi-decidable. However, with no function symbols, STRIPS-style planning is decidable, regardless of whether or not the planning domain is fixed in advance (Erol et al., 1992). Thus:

**Theorem 7** There exists HTN planning domains that can not be represented by any finite number of STRIPS-style operators.

Another way of comparing expressive power of two languages is based on model-theoretic semantics, which we do in (Erol et al., 1994a).

The power of HTN planning comes from two things: (1) allowing multiple tasks and arbitrary constraint formulas in task networks, (2) compound tasks. Allowing multiple tasks and arbitrary formula provides flexibility—but if all tasks were either primitive or goal (STRIPS-style) tasks, these could probably be expressed with STRIPS-style operators (albeit clumsily and using an exponential number of operators/predicates). Compound tasks provide an abstract representation for sets of primitive task networks, similar to the way non-terminal symbols provide an abstract representation for sets of strings in context-free grammars.

**Conclusion**

Our results show that handling interactions among non-primitive tasks is the most difficult part of HTN planning. In particular, if subtasks in the expansions for different tasks can be interleaved, then planning is undecidable, even if no variables are allowed.

We have investigated several conditions on the planning problem, such as restricting task-networks to contain a single non-primitive task or to be totally ordered. Those restrictions reduced the complexity significantly, because they limited the interactions among tasks.

Our comparison of the complexity of HTN planning and STRIPS-style planning demonstrates that HTN planners can represent a broader and more complex set of planning problems and planning domains. The transformations from HTN planning problems to STRIPS-style planning problems have revealed that STRIPS-style planning is a special case of HTN planning, and that the relation between them is analogous to the relation between context-free languages and regular languages.

---

4(Erol et al., 1994b) includes several complexity results similar to those in this paper, for the case when $\mathcal{D}$ is fixed.

5Since STRIPS-style planning does not include methods, a STRIPS-style planning domain is simply a set of operators.

6In proving this theorem, we use the standard assumption that the STRIPS operators do not contain function symbols, nor do the HTN operators.
